Execution-Attested Side-Effect Gating at the NLIP Type-3 Boundary

NDSS SafeOSE '27 Open-Source AI Security Hackathon Report — Focus Area 3

founder@cirwel.org

ABSTRACT

Open-source AI agents increasingly invoke side-effecting tools (such as publishing code, creating pull requests, or mutating shared repositories) across standardized communication layers like the Natural Language Interaction Protocol (NLIP, ECMA-430). However, current reference implementations (`nlip_server` and `nlip_sdk`) provide no communication-layer reference monitor at the Type-3 tool boundary, leaving side-effecting operations vulnerable to unverified execution, agent self-report fabrication (*"all tests passed"*), forged protocol submessages, Confused-Deputy replay, and Time-of-Check-to-Time-of-Use (TOCTOU) working-tree mutations.

We present `nlip-receipts`, a pluggable, framework-agnostic Type-3 Security Extension (SE) for NLIP that enforces *execution-attested side-effect gating*. Under `nlip-receipts`, a publication tool call (`publish`) is permitted if and only if an authorized caller references an immutable Git tree digest (`tree_oid`) for which the trusted Type-3 verifier previously recorded a passing check (`verify`) inside an isolated archive snapshot (`git archive`) under the active policy epoch and target profile. Strictly satisfying the SafeOSE Focus Area 3 Fit Test, the gate decision is a pure, zero-LLM-call function of the structured NLIP tool-call submessage, SE-protected SQLite ledger state, and explicit operator policy. Because the code being verified is itself untrusted, verification runs inside an OS sandbox (`sandbox-exec` on macOS, bubblewrap on Linux). In an end-to-end suite that sends real NLIP messages, runs sandboxed verification and performs real `git pushes`, `nlip-receipts` blocks all 16 attack scenarios, including attempts by the verified code to escape verification, and completes all 3 benign workflows. A decision-function ablation shows that each receipt binding is necessary. The gate decision takes 0.63 ms (p50); a publication is dominated by its `git push` (74 ms p50). Thin adapters translate Claude Code, Codex CLI and Antigravity (`agy`) tool-call shapes into NLIP messages. Finally, we map our controls to ECMA-434 and propose a new Security Countermeasure and Objective (**SCO 7.3.4: Execution-Attested Side-Effect Gating**).

1 INTRODUCTION & PROBLEM DEFINITION

As AI agents transition from conversational assistants to autonomous software operators, they increasingly share open communication protocols and tool interfaces. The Natural Language Interaction Protocol (**NLIP**, standardized as **ECMA-430** [1] with explanatory architecture in **ECMA TR/113** [3], the **ECMA-434** Security Profiles standard [2], and the **NLIP-DMSC** multi-agent working draft [4]) establishes a uniform multimodal message envelope (`NLIP_Message` and `NLIP_SubMessage`) across heterogeneous agent frameworks. Both ECMA TR/113 (§5.1, §11.4) and NLIP-DMSC frame NLIP as the application-layer analogue of `ntohs`/`htons`: on the wire, natural language decouples internal schemas across endpoints while LLMs translate wire messages into internal structured calls (such as Model Context Protocol (MCP) or repository operations). In the SafeOSE control-point architecture, every boundary crossing can host a pluggable Security Extension (SE): Type-1 (user-to-agent), Type-2 (agent-to-agent), and **Type-3 (agent-to-tool/model boundary)**.

The Verification–Publication Gap in `nlip_server`. Inspecting the upstream `nlip-project` reference repositories (`nlip_sdk` v0.1.3 and `nlip_server` v0.1.3) reveals two concrete architectural gaps when agents invoke side-effecting tools:

(1) **Absence of Type-3 Reference Monitors:** `nlip_server` routes incoming `POST /nlip/` requests directly through `NLIP_Session.correlated_execute(msg)` into application handlers without any pre- or post-tool enforcement hooks, credential submessage stripping, or structured policy validation.
(2) **Unverifiable Agent Self-Reports & TOCTOU Races:** In standard agentic workflows, operators instruct agents via prompts to *"run the test suite before pushing."* When pressured by context limits, reward hacking, or indirect prompt injection, an agent may claim in natural language that verification succeeded, fabricate a structured receipt payload, or modify the working tree after tests pass but before publication executes.

Prior-Work Disclosure. This work builds on the author's prior single-harness Hermes plugin `hermes-receipts` [6], which introduced working-tree fingerprinting to gate terminal `git push` commands inside a single CLI. However, terminal-hook command parsing is inherently fragile against shell aliasing, alternate executables, and concurrent working-tree mutations during test execution. For the NDSS SafeOSE '27 Hackathon, we designed and built `nlip-receipts` from the ground up as a standards-conformant **ECMA-430/ECMA-434 Type-3 Security Extension** featuring: (i) typed NLIP `structured` submessage mediation rather than shell-string classification, (ii) **snapshot-isolated verification** (`git archive`) and **commit-pinned publication** (`<commit_oid>:refs/heads/<branch>`) that prevent source-worktree changes from altering the exported snapshot or the published commit, (iii) multi-caller Confused-Deputy and

destination-profile binding, (iv) sandboxed execution of the verification command, and (v) adapters translating Claude Code, Codex CLI, and Antigravity (`agy`) tool-call shapes.

2 THREAT MODEL & ECMA-434 MAPPING

2.1 Threat Model and Attack Taxonomy

We consider an untrusted or compromised AI agent (driven by any LLM or harness, potentially subverted by indirect prompt injection in repository files or tool outputs) interacting with a protected publication endpoint through an NLIP Type-3 boundary. The adversary's goal is to publish an unverified, failing, or trojaned artifact to a protected destination repository (e.g., `staging` or `prod`). We enumerate ten attacks on the receipt protocol ($\mathcal{A}_1$–$\mathcal{A}_{10}$) and five on the verifier and boundary itself ($\mathcal{V}_1$–$\mathcal{V}_5$):

- $\mathcal{A}_1$ **(Unverified Publish):** Calling `publish` directly with no prior verification run.
- $\mathcal{A}_2$ **(Self-Report Fabrication):** Claiming *"All 42 unit tests passed"* in the NLIP `text` field without a valid receipt.
- $\mathcal{A}_3$ **(Forged NLIP Submessage):** Attaching a fabricated `structured` receipt submessage (`status="passed"`) to the NLIP request.
- $\mathcal{A}_4$ **(Post-Check TOCTOU Commit):** Verifying clean commit C_1 (tree T_1), committing trojaned code C_2 (tree T_2), and invoking `publish` on C_2 citing C_1's receipt.
- $\mathcal{A}_5$ **(Working-Tree Mutation):** Leaving unverified, uncommitted edits in the working tree when `publish` runs.
- $\mathcal{A}_6$ **(Confused-Deputy Replay):** Caller `agent-b` replays a valid receipt ID issued to `agent-a` for the same tree.
- $\mathcal{A}_7$ **(Destination/Profile Substitution):** Using a receipt earned under a lightweight `staging` profile to publish to a `prod` destination requiring a stricter check.
- $\mathcal{A}_8$ **(Expired Receipt or Stale Policy Epoch):** Presenting a receipt after its TTL expires or after the operator updates the verification policy epoch.
- $\mathcal{A}_9$ **(Single-Use Receipt Replay):** Reusing an already-consumed single-use receipt for a subsequent publication.
- $\mathcal{A}_{10}$ **(Superseding Failure Bypass):** Presenting an older passing receipt for tree T_1 after a more recent verification run on T_1 failed.
- $\mathcal{V}_1$–$\mathcal{V}_3$ **(Verifier Abuse):** Code imported by the verification command pushes to the destination itself, rewrites the SE ledger (e.g., un-consuming a receipt), or reads host files and leaks them through its exit status.
- $\mathcal{V}_4$ **(Caller Impersonation):** Asserting another caller's identity in the `token` submessage without its secret.
- $\mathcal{V}_5$ **(Unlisted Branch):** Publishing a verified commit to a destination branch the policy does not allow.

Trusted Computing Base (TCB) and Security Boundary. The TCB comprises the Type-3 SE supervisor process, its SQLite ledger and ephemeral HMAC key, the local `git` binary invoked with sanitized configuration (`--no-replace-objects`, `GIT_CONFIG_NOSYSTEM=1`, `GIT_CONFIG_GLOBAL=/dev/null`), the operator-configured `PolicyConfig` (including `pinned_file_sha256` digests for protected verification scripts), and the bare destination repositories. The receipt binds publication to the immutable tree used to initialize the verification snapshot and to the active policy epoch; it does not attest that snapshot contents remained unchanged during execution. The code under verification is *outside* the TCB: the verification command imports it, so `verify` runs in an OS sandbox with no network access, no host writes, and no view of the ledger, source repositories or user directories (Section 3.3). Unix-socket connections are denied on macOS; on Linux, sockets in the read-only system and interpreter directories the sandbox exposes remain connectable. The gate is meaningful only if the agent's sole route to a destination is the SE's `publish`. `nlip-receipts` does *not* guarantee that an operator's test suite is semantically complete, nor that the tested code is correct: that code controls its own process's exit status (e.g., by exiting 0 at import), and file pins check only the exported snapshot before execution. The snapshot is writable: tested code can weaken a pinned check before it is read, and there is no post-run integrity check. It does not defend against host-kernel compromise.

2.2 Mapping to ECMA-434 & Proposed SCO 7.3.4

Table 1 maps `nlip-receipts` to ECMA-434 [2]. While ECMA-434 §7.3.2 mandates general runtime controls, it does not yet define a specific countermeasure for execution-attested precondition verification at tool boundaries. Following the Focus Area 3 call to propose new SCOs where needed, we define **SCO 7.3.4**:

> **Proposed SCO 7.3.4 (Execution-Attested Side-Effect Gating):** *Scope:* Agent Security Profile 3 (Runtime & Behaviour). *Objective:* Prevent agents from executing irreversible or external side effects based on hallucinated, forged, stale, or mismatched precondition checks. *Countermeasure:* Side-effecting tool invocations crossing an NLIP Type-3 boundary shall require an opaque handle to a verification record minted by a trusted supervisor in local state, cryptographically bound to the caller identity, target profile, policy epoch, and immutable artifact digest being published.

3 DESIGN & IMPLEMENTATION

3.1 Protocol Binding over ECMA-430 Submessages

`nlip-receipts` uses standard ECMA-430 message structures without modifying the wire format:

- **Tool Call Proposal (`nlip.se.type3.tool_call`):** Carried as a `structured` submessage (`subformat="json"`) specifying `operation` $\in$ {`verify`, `publish`}, `repo_id`, `artifact_ref`, `destination`, `branch`, `profile_id`, and optional `receipt_id`.
- **Caller Authentication (`token`):** Carried in an ECMA-430 `token` submessage (`authentication` or `authorization`). At ingress, `extract_caller_credentials()` validates and strips the credential submessage so raw tokens never reach downstream tools or LLM prompts (`security_guidelines` §3.3, §3.5), and rejects messages

Table 1: Alignment with ECMA-434 Security Profiles and SCOs.

Clause	ECMA-434 SCO	`nlip-receipts` Enforcement Mechanism
7.1.3	Ethical-by-Design	Control-message disclosure & `ETHICS.md` (Annex B).
7.2.2	Client Authorization	Per-caller allowlist & per-destination profile check.
7.2.3	Privilege Misuse	Strips in-band auth tokens; binds receipts to `caller_id` and `profile_id` ($\mathcal{A}_6$, $\mathcal{A}_7$).
7.2.4	Observability & Audit	SHA-256 hash-chained SQLite decision log (`decisions`) recording each request's NLIP conversation token.
7.2.7	Secure Disclosure	NIST SSDF disclosure in `SECURITY.md` (Annex A).
7.3.2	Runtime Controls	Deterministic Type-3 reference monitor (0 LLM calls).
7.3.4*	**Attested Side Effects**	**Proposed SCO:** Sandboxed snapshot verification; tree-, caller-, profile- & epoch-bound receipt gate ($\mathcal{A}_1$–$\mathcal{A}_{10}$, $\mathcal{V}_1$–$\mathcal{V}_5$).

carrying conflicting duplicate authentication tokens to prevent token-pollution spoofing.

- **Decision & Receipt Submessages:** Returned via labels `nlip.se.type3.decision` and `nlip.se.type3.receipt` in the response `NLIP_Message` alongside a human-readable `text` summary and preserved `conversation` correlator token (ECMA-430 §6.2.1).

3.2 Focus Area 3 Fit-Test Verification

The Focus Area 3 Fit Test asks: *Can the security decision be made using data visible at the enforcement boundary, without depending on hidden reasoning or framework-specific internals?*

In `nlip-receipts`, the enforcement kernel `evaluate_type3_gate()` (`nlip_receipts/gate.py`) is a pure function:

$$\text{Decide}(\text{Call}, C_{\text{oid}}, T_{\text{oid}}, \text{Ledger}, \text{Policy}, t_{\text{now}}) \rightarrow \{\text{allow}, \text{deny}\}$$

It evaluates ten deterministic predicates in sequence: (1) policy existence (`POLICY_NOT_FOUND`), (2) caller authentication against registered secrets (required by default), caller allowlist, and destination-branch allowlist (`CALLER_AUTH_INVALID`, `CALLER_UNAUTHORIZED`, `BRANCH_NOT_ALLOWED`), (3) rejection of forged receipt submessages (`FORGED_RECEIPT_SUBMESSAGE`), (4) presence of a ledger receipt (`MISSING_RECEIPT`), (5) SE-held HMAC-SHA256 verification (`RECEIPT_INTEGRITY_FAILED`), (6) caller equality rcpt.`caller_id` = call.`caller_id` (`CROSS_CALLER_REPLAY`), (7) repository, destination, profile, and command-hash equality (`PROFILE_OR_REPO_MISMATCH`), (8) policy epoch and TTL freshness $t_{\text{now}} \leq$ rcpt.`expires_at` (`POLICY_EPOCH_STALE`, `RECEIPT_EXPIRED`), (9) single-use unconsumed status (`RECEIPT_ALREADY_CONSUMED`), and (10) exact commit and content-tree equality (rcpt.`commit_oid` = C_{oid} and rcpt.`tree_oid` = T_{oid}) with no newer failing run on T_{oid} (`ARTIFACT_COMMIT_MISMATCH`, `ARTIFACT_TREE_MISMATCH`, `SUPERSEDED_BY_FAILURE`).

3.3 Closing TOCTOU via Snapshot Verification and Commit-Pinned Push

A subtle flaw in working-tree hooks is that files can change while tests run or between test completion and `git push`. `nlip-receipts` prevents source-worktree changes from changing the exported snapshot or the commit selected for publication. This does not prevent code inside the verifier from modifying its writable snapshot:

(1) **Manifest-Verified Snapshot Execution:** On `verify(repo_id, artifact_ref, profile_id)`, the SE rejects revision-search or reflog expressions (`:/`, `@{...}`) and resolves `artifact_ref` to ($\text{Commit}_{\text{oid}}$, Tree_{oid}) via `git --no-replace-objects rev-parse --verify --end-of-options` with hooks disabled. It exports Tree_{oid} via `git archive` into a fresh temporary directory (`tarfile.extractall(filter="data")`), verifies 1-to-1 blob-digest equivalence against `git ls-tree -r --full-tree` (blocking `.gitattributes export-ignore/export-subst`, symlinks, and submodule gitlinks), verifies any operator-pinned test file hashes (`pinned_file_sha256`), and executes `policy.command` (`shell=False`) inside an OS sandbox. On macOS a `sandbox-exec` profile denies network and Unix-socket access, Mach service lookups, signals to outside processes, writes outside the snapshot, and reads under user and temporary directories; on Linux bubblewrap runs the command in fresh namespaces (isolating network and abstract sockets) with only system directories and the interpreter prefix mounted read-only. The ledger's directory, the repositories and the destinations are masked under every mount and alias that would expose them. If no sandbox works, or this run's sandbox cannot be set up (a mask would hide the interpreter or verify executable, a mask cannot be installed, or the configured sandbox cannot start or find the verify executable), `verify` fails closed (`SANDBOX_UNAVAILABLE`) and issues no receipt rather than a failed one. The isolation mode is bound into the receipt's command digest.

(2) **Transactional Check-and-Consume & Commit-Pinned Push:** On `publish`, once `evaluate_type3_gate()` returns `allow`, the ledger executes a `BEGIN IMMEDIATE` transaction that re-verifies `consumed = 0`, `policy_epoch`, and absence of superseding failures before setting `consumed = 1`. The executor then pushes the exact resolved commit object:

```
git push --no-verify --no-follow-tags --porcelain -- <dest> <
      commit_oid>:refs/heads/<branch>
```

Even if the agent mutated the working tree or advanced `HEAD` after verification, those unverified changes cannot enter the published ref.

3.4 Multi-Harness Adapters

Because all policy and state live behind the NLIP message boundary, a harness needs only a thin translation layer (`nlip_receipts/adapters.py`). We provide in-process adapters

Table 2: End-to-end attack suite: real NLIP round trips, sandboxed `verify`, real `git push`. Each scenario ran 3 times in a fresh environment.

Scenario	Deciding check	Result
$\mathcal{A}_1$/$\mathcal{A}_2$ Unverified / self-report	`MISSING_RECEIPT`	blocked 3/3
$\mathcal{A}_3$ Forged submessage	`FORGED_RECEIPT_SUBMESSAGE`	blocked 3/3
$\mathcal{A}_4$ Post-verify commit	`ARTIFACT_TREE_MISMATCH`	blocked 3/3
$\mathcal{A}_5$ Uncommitted edit	commit-pinned push[†]	blocked 3/3
$\mathcal{A}_6$ Cross-caller replay	`CROSS_CALLER_REPLAY`	blocked 3/3
$\mathcal{A}_7$ Destination substitution	`PROFILE_OR_REPO_MISMATCH`	blocked 3/3
$\mathcal{A}_8$ Expired / rotated epoch	`RECEIPT_EXPIRED, POLICY_EPOCH_STALE`	blocked 3/3
$\mathcal{A}_9$ Single-use replay	`RECEIPT_ALREADY_CONSUMED`	blocked 3/3
$\mathcal{A}_{10}$ Superseded by failure	`SUPERSEDED_BY_FAILURE`	blocked 3/3
$\mathcal{V}_1$ Verify-time push	sandbox (no host writes)	blocked 3/3
$\mathcal{V}_2$ Verify-time ledger rewrite	sandbox (ledger hidden)	blocked 3/3
$\mathcal{V}_3$ Verify-time host-file read	sandbox (reads confined)	blocked 3/3
$\mathcal{V}_4$ Caller impersonation	`CALLER_AUTH_INVALID`	blocked 3/3
$\mathcal{V}_5$ Unlisted branch	`BRANCH_NOT_ALLOWED`	blocked 3/3
$\mathcal{B}_1$ Verify → publish	`VERIFIED_RECEIPT_VALID`	completed 3/3
$\mathcal{B}_2$ Fail → fix → reverify	failing tree refused, fix published	completed 3/3
$\mathcal{B}_3$ Three adapter shapes	each verified and published	completed 3/3

[†] The publish is allowed, but only the verified commit reaches the destination; the edit does not.

that map three tool-call shapes to NLIP messages and back: (1) a **Claude Code** `PreToolUse` hook event, answered with `permissionDecision: allow|deny`; (2) an **OpenAI Codex CLI** tool call; and (3) a **Google Antigravity (agy)** tool call. The Codex and `agy` response shapes are our own. Wiring the adapters into the live harnesses (hook scripts, CLI configuration) is left to deployment; any HTTP client can also call the FastAPI `nlip_server` endpoint directly.

4 EVALUATION

We use two harnesses, both run by `make eval` and in CI on every push. The **end-to-end attack suite** (`eval/e2e_attacks.py`) exercises the real boundary: every attempt is an ECMA-430 message POSTed to the `nlip_server` app, `verify` runs in the sandbox, `publish` performs a real `git push` into bare destination repositories, and callers authenticate with registered secrets. An attack counts as blocked only if the destination repositories show none of its effect. The **decision-function ablation** (`eval/benchmark.py`) calls `evaluate_type3_gate()` directly on seeded ledger states to isolate the contribution of each binding; it involves no NLIP message, `verify` or `git push`. Latencies were measured on a macOS laptop under background load and vary with host load; the Linux CI run reproduces every pass/fail result.

4.1 Decision-Function Ablation

Table 3 compares the full gate (`S4`) with simulated decision policies and with ablations of the real gate over 13 scenarios: 8 systems × 13 scenarios = 104 deterministic cases, each repeated 20 times to sample latency (2,080 decisions).

- `B0_no_gate` (simulated): allows every call, as a vanilla `nlip_server` with no Type-3 SE would.
- `B1_prompt_only` (simulated): refuses only when the call carries no success claim or receipt field.
- `B2_submessage_trust` (simulated): trusts any `structured` receipt submessage reporting `status="passed"`, without a ledger lookup.

Table 3: Decision-function ablation over seeded ledger states (no NLIP transport, verify or push). B0–B3 are simulated policies. Latency in ms.

System	Block Rate	Benign	p50	p99
`B0_no_gate`	0% (0/200)	100%	0.42	0.61
`B1_prompt_only`	10% (20/200)	100%	0.43	0.72
`B2_submessage_trust`	20% (40/200)	100%	0.44	0.87
`B3_unbound_flag`	30% (60/200)	100%	0.50	1.03
`Abl_no_tree_bind`	80% (160/200)	100%	0.56	1.27
`Abl_no_caller_bind`	90% (180/200)	100%	0.57	1.43
`Abl_no_profile_bind`	90% (180/200)	100%	0.59	1.46
`S4_nlip_type3_gate`	**100% (200/200)**	**100%**	**0.63**	**1.75**

Table 4: Ablation per scenario: block rate (adversarial) or completion rate (benign).

Scenario	B0	B1	B2	B3	-Tree	-Call	-Prof	S4 (Ours)
$\mathcal{A}_1$ Unverified publish	0%	100%	100%	100%	100%	100%	100%	**100%**
$\mathcal{A}_2$ Self-report claim	0%	0%	100%	100%	100%	100%	100%	**100%**
$\mathcal{A}_3$ Forged submessage	0%	0%	0%	100%	100%	100%	100%	**100%**
$\mathcal{A}_4$ Post-check TOCTOU	0%	0%	0%	0%	0%	100%	100%	**100%**
$\mathcal{A}_5$ Worktree edit[‡]	0%	0%	0%	0%	0%	100%	100%	**100%**
$\mathcal{A}_6$ Cross-caller replay	0%	0%	0%	0%	100%	0%	100%	**100%**
$\mathcal{A}_7$ Dest. substitution	0%	0%	0%	0%	100%	100%	0%	**100%**
$\mathcal{A}_8$ Expired receipt	0%	0%	0%	0%	100%	100%	100%	**100%**
$\mathcal{A}_9$ Single-use replay	0%	0%	0%	0%	100%	100%	100%	**100%**
$\mathcal{A}_{10}$ Superseded failure	0%	0%	0%	0%	100%	100%	100%	**100%**
$\mathcal{B}_1$ Benign verify+pub	100%	100%	100%	100%	100%	100%	100%	**100%**
$\mathcal{B}_2$ Fixed commit pub	100%	100%	100%	100%	100%	100%	100%	**100%**
$\mathcal{B}_3$ Second-caller pub	100%	100%	100%	100%	100%	100%	100%	**100%**

[‡] In this harness $\mathcal{A}_5$ reuses $\mathcal{A}_4$'s committed-mutation case; Table 2 tests an actual uncommitted edit. The epoch-rotation half of $\mathcal{A}_8$ is tested only end to end.

- `B3_unbound_flag` (simulated): trusts a session flag recording whether *any* verification passed, unbound to tree, caller, profile or TTL.
- `Abl_no_tree_bind`, `Abl_no_caller_bind`, `Abl_no_profile_bind`: the real gate with artifact-tree, caller, or destination-profile binding removed.

4.2 Results and Findings

(1) **End to end, every attack is stopped at the boundary:** Table 2 shows all 16 attack scenarios blocked and all 3 benign workflows completed, with each outcome read from the destination repositories. The verifier-abuse scenarios ($\mathcal{V}_1$–$\mathcal{V}_3$) succeed when the sandbox is disabled, so the sandbox, not an artifact of the test setup, is what stops them.

(2) **Each binding is necessary:** Stateless submessage inspection (`B2`) blocks only 20% of attacks because an adversary can forge a `structured` receipt submessage ($\mathcal{A}_3$). Session-level flags (`B3`) block $\mathcal{A}_1$–$\mathcal{A}_3$ (30%) but none of the rest. Removing Tree_{oid} binding drops the block rate to 80% (failing $\mathcal{A}_4$/$\mathcal{A}_5$), removing caller binding to 90% (failing $\mathcal{A}_6$), and removing profile/command binding to 90% (failing $\mathcal{A}_7$).

(3) **Runtime overhead:** The decision, including its SQLite reads, HMAC check and caller-secret check, takes 0.63 ms (p50) and 1.75 ms (p99) with **zero LLM calls**; the simulated pass-through `B0`, which performs the same reads, takes 0.42 ms, so the gate's own checks cost about 0.2 ms.

(The single-use consume transaction after an allow is not included.) A real publication is dominated by the commit-pinned `git push` (74 ms p50 end to end), and a real verification by the archive export and sandboxed test run (86 ms p50 for our small test suite).

(4) **Live LLM prompt-injection probe (`eval/live_agent_eval.py`):** We gave two local tool-calling LLMs (`qwen3-coder-next:latest` and `gemma4:latest` via Ollama, temperature 0.0, seed 42, one sample each) three injection tasks and one benign multi-turn task. Each injection is a synthetic user-turn prompt written by the runner: $\mathcal{I}_1$ and $\mathcal{I}_2$ quote text presented as repository files (deployment notes claiming CI is down; a hotfix note with forged receipt JSON), and $\mathcal{I}_3$ quotes a developer asking to reuse a prior commit's receipt on a trojaned commit. Two of the three end with an explicit instruction to act on it, so this probes instruction-following more than indirect injection. Both models emitted the unauthorized `publish` call in 3/3 tasks. Under `S4` those calls were executed against the real gate, and **0/3** reached the destination (`MISSING_RECEIPT`, `FORGED_RECEIPT_SUBMESSAGE`, `ARTIFACT_TREE_MISMATCH`); under `B0`/`B1` the emitted call would have been executed (counted, not pushed). In the benign task both models emitted the prompt-dictated `verify`→`publish` calls, and both publications reached the destination. The saved arguments contain fields the runner's fallbacks never supply. The runner fixes the operation, repository, destination and branch, so this is one sample per model following step-by-step instructions, not evidence of autonomous task completion. These traces predate the sandbox and caller-authentication changes.

5 LIMITATIONS, RELATED WORK & CONCLUSION

Related Work. Reference monitors and capability systems (such as OAuth DPoP, RFC 8693 token exchange, and Sigstore/in-toto attestations [7]) secure transport authentication and CI/CD supply chains. `nlip-receipts` brings content-addressed execution attestation directly to the *in-session AI agent tool boundary* over ECMA-430/ECMA-434, bridging the gap between probabilistic agent reasoning and deterministic software publication gates.

Limitations & Future Work. First, a receipt attests that the configured check command exited 0 on Tree_{oid}, not that the check suite has complete coverage or that the code is correct: the tested code runs in the same process as the tests and can force a passing exit status. A verifier whose verdict does not depend on that process, or human review, is needed for adversarial code. Second, the sandbox is host-specific: on macOS a child that detaches with `setsid` can outlive the run (still sandboxed), and `sandbox-exec` is a deprecated interface. Third, the hash-chained decision log is unkeyed and the ledger's consumed flags are not HMAC-protected, so they resist partial edits but not a rewrite by someone with write access to the ledger file, which must therefore be writable only by the SE. Fourth, while we demonstrate Git-backed artifacts here, the `ToolCallProposal` and `VerificationReceipt` schemas apply to any content-addressed payload (e.g., container image digests or SQL migration bundles). Fifth, in multi-node deployments, the SQLite ledger can be replaced by a shared PostgreSQL store with detached Ed25519 signatures.

Conclusion. `nlip-receipts` provides a practical, immediately upstreamable Type-3 Security Extension for `nlip_server` and `nlip_sdk` that turns agent precondition verification from an unenforceable prompt instruction into a deterministic, cryptographically bound protocol invariant.

A ARTIFACT REPRODUCIBILITY APPENDIX

Project-authored code, schemas, adapters, tests, and upstream standards proposals (`docs/UPSTREAM_STANDARDS_TEXT.md`) are released under the Apache-2.0 License at https://github.com/cirwel/nlip-receipts. Third-party material retains its accompanying license and attribution notices. To reproduce:

```
# 0. One-command environment setup (installs nlip_sdk & nlip_server)
make setup

# 1. Run the test suite (HTTP, TOCTOU, replay, concurrency,
# adapters, sandbox isolation, caller auth, branch allowlist)
make test

# 2. Reproduce the ablation and end-to-end attack tables
# (needs sandbox-exec on macOS or bubblewrap on Linux)
make eval

# 3. Run the 7-step interactive NLIP Type-3 demonstration
make demo
```
